How I use ggplot2

Paul Schmidt

2023-11-14

A brief introduction to ggplot2. Be warned: This chapter provides detailed insight into certain aspects, while other components are not discussed at all.

Table of contents

1 Before we start

1.1 Who this is for

This tutorial serves as an introductory guide to ggplot2, tailored specifically for beginners with no prior exposure to ggplot2. However, it's worth mentioning that as we delve deeper into the subject, we'll employ both BaseR and tidyverse code for some data preparations.

In addition, this ggplot2 guide reflects my personal approach and application of visualization techniques, focusing on the disciplines that align with the theme of this website - from agricultural sciences to experimental data from biology or life sciences at large. This tutorial, therefore, may not encompass all facets of ggplot2, but rather those elements that I frequently utilize in these specific domains.

1.2 Other resources

Here are some other ggplot2 tutorials and resources that I like:

- Chapter 3: Data Visualisation in (Wickham and Grolemund 2017)
- Cédric Scherer's (2022a) A ggplot2 tutorial for beautiful plotting in R
- Cédric Scherer's (2022b) Graphic Design with ggplot2
- Andrew Heiss' (2023) Data visualization with R
- Claus Wilke's (2019) Fundamentals of Data Visualization

1.3 Packages to install & load

We are using the `p_load()` function of the {pacman} package to install and load all necessary packages for this tutorial.

```r
pacman::p_load(
  ggplot2,
  ggrepel,
  ggtext
  )
```
1.4 Showcase
Here are some beautiful ggplots

2 Let's start

Let us start by creating a plot that requires a minimum amount of code, but is still informative. We make use the `PlantGrowth` data, which is directly accessible in R.

```
ggplot(data = PlantGrowth,
       mapping = aes(y = weight, x = group)) +
  geom_point()
```

```
ggplot(data = PlantGrowth) +
  aes(y = weight, x = group) +
  geom_point()
```

Actually, you can see we created the same plot twice using slightly different code. Apologies for immediately confusing you with this, but it would be even more confusing if we postpone this topic.

Let's try to understand the general approach by looking at the first version of the code. The code for any ggplot always starts with the `ggplot()` function and then **layers** are added to it via the `+` operator.

The `data =` argument in `ggplot()` is where you specify the dataset you want to visualize. Think of it as telling ggplot "Here is the data I want you to work with."

The `mapping = aes()` argument is where you define the aesthetic mappings, like which columns of the data should be represented on the x and y axes. It's like giving ggplot specific instructions on "How should you represent this data?" For instance, `mapping = aes(x = column1, y = column2)` would tell ggplot to use `column1` for the x-axis and `column2` for the y-axis.

So, together, these two arguments form the fundamental instructions for any ggplot: "Here is my data, and this is how I want you to represent it."

Looking at our two versions of code that result in the same plot, you can see that they only differ in how the `aes()` is included. The far more common approach is to include it inside the `ggplot()` function as in the first version. However, I am not the only one who argues that the second version is simply easier to read, which is why I am using it. Other than that, there is no difference between the two versions.

Finally, there is `geom_point()`. This function, known as a geometric object or "geom", represents the type of plot you want to create. In ggplot2, every type of plot is associated with a specific geom function. For our example,`geom_point()` is used to create a scatter plot, draws a point for each observation. The `geom_point()` function is added to the base `ggplot()` call using the `+` operator, just like the other layers. In this way, it's as if we're telling ggplot: "And here is the type of plot I want you to create.". Again - it already knows *where* to draw the points because we told it about the data and aesthetic mapping.

Other geoms you might use include `geom_boxplot()` for boxplots, `geom_line()` for line graphs, and many more. Each geom function has its own set of aesthetics and other arguments that you can specify to customize your plot. By using these different geoms, you can create a wide variety of plots to meet your specific data visualization needs.

Now you understand the absolute minimum of how to create a ggplot.

> 💡 Additional Resources
>
> - List of all `geom_*()` functons

3 Saving and reusing plots

In ggplot2, you can save your plots into an object. This allows you to reuse and modify your plots without having to rewrite all the code. This is particularly useful when you are building complex plots layer by layer.

Let's take the plot we have created so far. Instead of writing the code for all the layers every time, we can save the plot into an object and then add new layers to this object. This way, we can focus on the new layers we are adding, making our code more readable and manageable.

Here's how we can do this:

```
myplot <- ggplot(data = PlantGrowth) +
  aes(y = weight, x = group) +
  geom_point()
```

Be aware that when running this code, you will not get to see the plot you just saved. Instead, you would need to run the `myplot` object to see the plot:

```
myplot
```
This approach of saving and reusing plots not only makes our code more readable and manageable, but also allows us to experiment with different layers and modifications without affecting our original plot.

From now on, we will use this approach in our tutorial. At the end of each main section, we will update `myplot` with the new layers we have discussed in that section. This will allow us to build our plot step by step, focusing on one aspect at a time.

4 Axes

In ggplot2, the `scale_x_*` and `scale_y_*` functions are used to control the appearance of the x and y axes, respectively. These functions allow you to set the scale type (continuous, discrete, etc.), the axis labels, the tick mark labels, and the range of values displayed on the axis.

Regarding the scale type, we need to use `scale_y_continuous()` (since `weight` is a continous, metric variable) and `scale_x_discrete()` (since `group` is a discrete, categorical variable) for our scatter plot.

4.1 Name

The `name =` allows you to change the axis titles.

```
myplot +
  scale_y_continuous(name = "Weight (g)") +
  scale_x_discrete(name = "Treatment Group")
```

4.2 Limits

The `limits =` argument in the scale_*_* functions allows you to specify the range of values displayed on the axis. This can be particularly useful when you want to focus on a specific part of your data. Let's see how this works in practice with our scatter plot example.

```
myplot +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, 7)
  ) +
  scale_x_discrete(
    name = "Treatment Group",
```

```
  limits = c("ctrl", "trt2")
)
```

```
myplot +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA)
  ) +
  scale_x_discrete(
    name = "Treatment Group",
    limits = c("trt1", "ctrl", "trt2")
  )
```

In the left plot, we use the `limits =` argument in `scale_y_continuous()` to set the y-axis to range from 0 to 7. This works as expected, showing all weights from 0 to 7. However, including only "ctrl" and "trt2" (i.e. the first and last level) in the `limits =` argument of in `scale_x_discrete()`, results in only these two groups being displayed on the x-axis. The key point here is that for a discrete scale, the `limits =` argument needs to include all the levels you want to display.

In the right plot, we again use the `limits =` argument in `scale_y_continuous()`, but this time we only specify the lower limit (0) and use `NA` for the upper limit. This tells ggplot2 to start the y-axis at 0 and end it at the maximum value in the data, which is the default behavior. For the x-axis, we provide all three levels ("trt1", "ctrl", "trt2") in the `limits =` argument of `scale_x_discrete()`. This not only ensures that all groups are displayed, but also allows us to control the order in which they appear.

This demonstrates how the `limits =` argument can be used differently in `scale_*_continuous()` and `scale_*_discrete()`. In a continuous scale, it defines the range of values, while in a discrete scale, it specifies which levels to include and their order.

In the end, it's important to note that setting the limits can exclude data outside the specified range from the plot. This means that the excluded data will not be considered when calculating statistics or generating geoms. In other words, while setting limits can help focus your plot on specific aspects of your data, it can also exclude important information. Always consider the implications of setting limits on your data visualization.
4.3 Breaks

The breaks = argument in these functions allows you to specify the locations of the tick marks on the axis.
```
myplot +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = c(0, 6)
  ) +
  scale_x_discrete(
    name = "Treatment Group"
  )
```

```
myplot +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = seq(0, 6)
  ) +
  scale_x_discrete(
    name = "Treatment Group"
  )
```

In the left plot, we use the `breaks =` argument in `scale_y_continuous()` to set the y-axis tick marks at 0 and 6. This really results in only two tick marks being displayed on the y-axis. While this is not typically useful for data representation, it serves to illustrate that the `breaks =` argument can be used to place tick marks at any specified values.

In the right plot, we use the `seq()` function in the `breaks =` argument to set the y-axis tick marks at every integer value from 0 to 6. This provides a more informative view of the data, as it allows us to see the weight values at regular intervals.

> **💡 Tip**
>
> Instead of having to manually write "6" in `breaks = seq(0, 6)` you can instead do this:
>
> - `breaks = seq(0, max(PlantGrowth$weight))` automatically finds the maximum value in the data
> - `breaks = scales::breaks_width(1)` makes use of the `breaks_width()` function in the {scales} package to simply define the width of the breaks
4.4 Labels

The `labels =` argument allows you to specify the text that is displayed for each tick mark on the axis. This can be particularly useful when the values in your data are not self-explanatory or when you want to use more descriptive labels.

```r
myplot +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = seq(0, 6)
  ) +
  scale_x_discrete(
    name = "Treatment Group",
    labels = c("Control", "Treatment 1", "Treatment 2")
  )
```
```
myplot +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = seq(0, 6)
  ) +
  scale_x_discrete(
    name = "Treatment Group",
    labels = c(
      ctrl = "Control",
      trt1 = "Treatment 1",
      trt2 = "Treatment 2"
    )
  )
```

In the first example, we simply provide a vector of labels. This works fine as long as the levels on the x-axis are in the same order as the labels in the vector. However, if the levels are not in the expected order, the labels will be associated with the wrong levels.

In the second example, we provide a named vector of labels. This ensures that the labels are correctly associated with their corresponding levels, regardless of the order of the levels. This is why using a named vector is often the safer option.

> 💡 Tip
>
> You can also use `labels =` on continuous axes, if you make use of the `label_*()` functions in the {scales} package. Here are some examples:
>
> - `labels = label_number()` displays numbers on your axis any way you want. E.g. `decimal.mark = "."` displays axis label 3.14 as 3,14 etc.
> - `labels = label_percent()` displays axis labels 0.05, 0.4 as 5%, 40% etc.
> - `labels = label_log()` displays axis labels 10, 100, 1000 as 10^1, 10^2, 10^3 etc.

4.5 Expand

The `expand =` argument in the scale_*_* functions allows you to control the expansion of the scale. This is particularly useful when you want to adjust the space between the plotted data

14

and the axes.

By default, ggplot2 adds a small amount of space around the data to ensure that the data doesn't overlap with the axes. However, there might be situations where you want to adjust this space. For instance, you might want to remove the space below the 0 on the y-axis.
```
myplot +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = seq(0, 6),
    expand = c(0, 0)
  ) +
  scale_x_discrete(
    name = "Treatment Group",
    labels = c(
      ctrl = "Control",
      trt1 = "Treatment 1",
      trt2 = "Treatment 2"
    )
  )
```
```
myplot +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = seq(0, 6),
    expand = expansion(mult = c(0, 0.05))
  ) +
  scale_x_discrete(
    name = "Treatment Group",
    labels = c(
      ctrl = "Control",
      trt1 = "Treatment 1",
      trt2 = "Treatment 2"
    )
  )
```

In the left plot, we use the `expand = c(0, 0)` argument in `scale_y_continuous()` to simply set the expansion to 0 on both sides of the scale. This removes all extra space around the data. However, this also results in the plot being cut off right at the maximum observation, which might not be desirable.

In the right plot, we use the `expansion()` function in the `expand =` argument. This function

allows us to set different expansion multipliers for the lower and upper limits of the scale. Here, we set the lower multiplier to 0 to remove the space below 0, and the upper multiplier to 0.05 to add a small amount (= 5%) of space above the maximum observation.

> 💡 Tip
>
> For a better understanding of how this expansion-thing works, I found this cheat sheet to be insightful.

We update our `myplot` according to what we just learned. To get a better overview, we recreate it from scratch:

```r
myplot <- ggplot(data = PlantGrowth) +
  aes(y = weight, x = group) +
  geom_point() +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = seq(0, 6),
    expand = expansion(mult = c(0, 0.05))
  ) +
  scale_x_discrete(
    name = "Treatment Group",
    labels = c(
      ctrl = "Control",
      trt1 = "Treatment 1",
      trt2 = "Treatment 2"
    )
  )
```
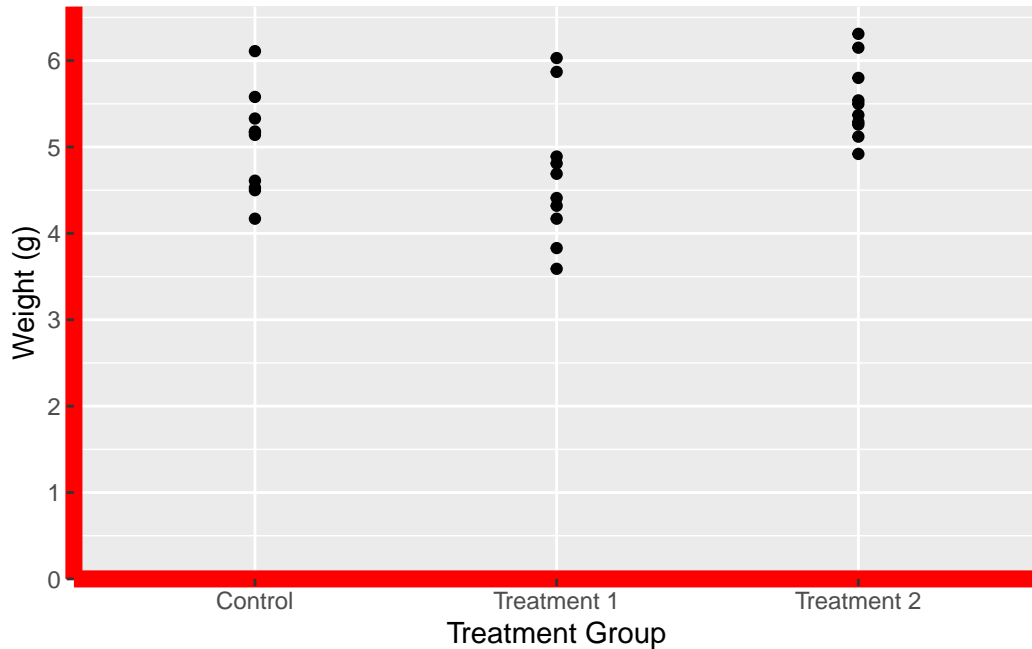

5 Theme

In ggplot2, the `theme()` function is a powerful tool that allows you to customize the non-data components of your plot. This includes the plot background, grid lines, axis lines, text, legend, and more. By using `theme()`, you can create plots that not only represent your data accurately, but also align with your personal or organizational style guidelines.

Let's take a look at two examples where we use `theme()` to modify the plot background and the axis lines.

```
myplot +
  theme(plot.background = element_rect(fill = "green"))
```

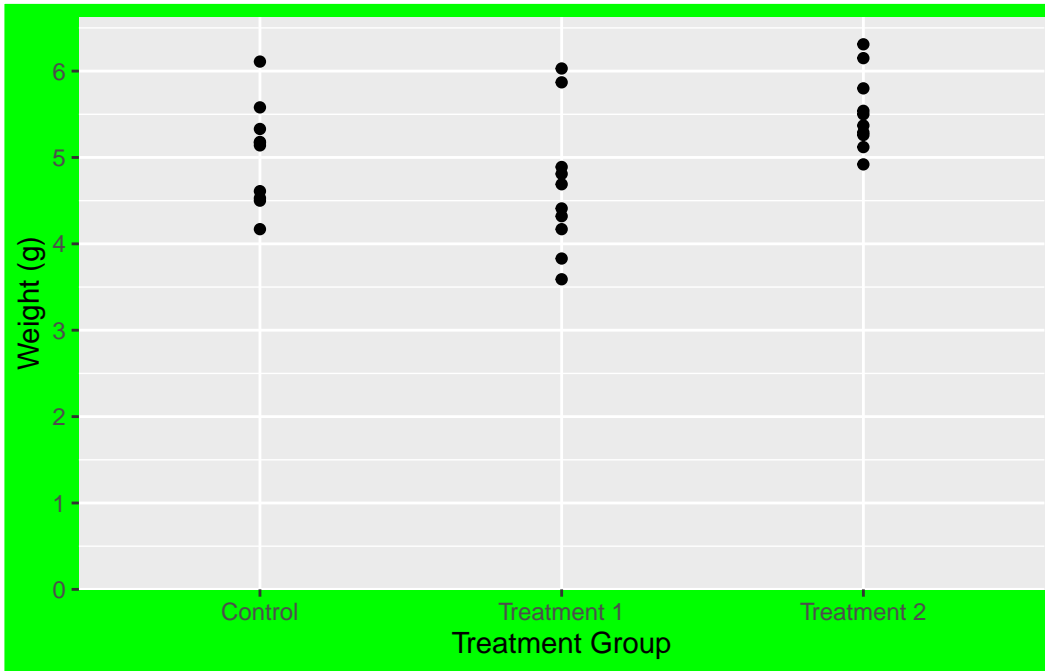

```
myplot +
  theme(axis.line = element_line(color = "red", linewidth = 3))
```

In the first example, we use `theme(plot.background = element_rect(fill = "green"))` to change the plot background to green. In the second example, we use `theme(axis.line = element_line(color = "red", linewidth = 3))` to change the color of the axis lines to red and increase their width. While these functions may seem a bit cryptic, the good news is that there are only four different theme elements: `element_blank()` draws nothing, and assigns no space, `element_rect()` for borders and backgrounds, `element_line()` for lines and `element_text()` for text.

While the `theme()` function provides a high level of customization, it can be time-consuming to manually specify every detail of your plot. To save time, ggplot2 provides several predefined "complete themes" that you can use. These themes have been professionally designed and provide a quick way to change the overall appearance of your plot.

The default theme in ggplot2 is `theme_grey()`. However, there are several other themes available, such as `theme_bw()`, `theme_classic()`, `theme_dark()`, and more. Let's take a look at two of these themes that I personally like:

```
myplot +
  theme_classic()
```
```
myplot +
  theme_bw()
```
Note that you can also first add a complete `theme_*()` and subsequently change individual aspects of it with via `theme()`.

Remember, while themes can greatly enhance the aesthetic appeal of your plots, the most important aspect of any plot is its ability to accurately and effectively convey information about your data. Always prioritize clarity and accuracy over aesthetic appeal when creating your plots.

> 💡 Additional Resources
>
> - List of all complete themes
> - Documenation of the `theme()` function

We update our `myplot` according to what we just learned. To get a better overview, we recreate it from scratch:

```r
myplot <- ggplot(data = PlantGrowth) +
  aes(y = weight, x = group) +
  geom_point() +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = seq(0, 6),
    expand = expansion(mult = c(0, 0.05))
  ) +
  scale_x_discrete(
    name = "Treatment Group",
    labels = c(
      ctrl = "Control",
      trt1 = "Treatment 1",
      trt2 = "Treatment 2"
    )
  ) +
  theme_classic()
```

6 Export

Once you have created a plot in ggplot2, you may want to export it as an image file. This can be useful for including the plot in a report, a presentation, or a website.

In RStudio, you can manually export your plots by clicking on the 'Export' button in the 'Plots' pane. This will open a dialog box where you can choose the format and settings for

your exported image.

However, a more flexible and reproducible way to export your plots is by using the `ggsave()` function provided by ggplot2. This function allows you to specify the details of the exported image directly in your code, ensuring that you can reproduce the exact same image in the future. The `ggsave()` function has several arguments that allow you to specify the details of the exported image:

```
ggsave(
  filename = "myplot.png",
  plot = myplot,
  path = "C:/Users/YourName/Documents",
  scale = 1,
  width = 6,
  height = 4,
  units = "cm",
  dpi = 300
)
```

- **filename:** This is the name of the file that you want to create. You should include the file extension (e.g., .png, .jpg, .pdf) in the filename. The file extension determines the format of the exported image.

- **plot:** This is the plot that you want to save. If you don't specify a plot, ggsave() will save the last plot that you created.

- **path:** This is the directory where you want to save the file. If you don't specify a path, ggsave() will save the file in your current working directory.

- **scale:** This is a scaling factor that is applied to the text and elements of the plot. A scale of 1 means that the plot is saved at its original size. A scale of 2 means that the plot is saved at twice its original size.

- **width, height:** These are the dimensions of the exported image. You can specify the dimensions in any units that you like (e.g., inches, cm, mm).

- **units:** This is the units in which the width and height are specified. The default is "in" for inches, but you can also use "cm" for centimeters, "mm" for millimeters, or "px" for pixels.

- **dpi:** This is the resolution of the exported image in dots per inch. A higher dpi will result in a higher-quality image, but the file size will also be larger. The default dpi is 300, which is suitable for most purposes.

In this example, we are saving `myplot` as a PNG file named "myplot.png" in the Documents directory. The plot is saved at its original size (scale = 1) and the dimensions of the image are 6 cm by 4 cm. The resolution of the image is 300 dpi.

> 💡 Tip
>
> If you want to open the image file you've just created directly on your computer, you can use the `system()` function in R. For instance, `system('open "FILENAME"')` will open the specified file. So, in our case, running `system('open "C:/Users/YourName/Documents/myplot.png"')` will open the PNG file we've just created, and it will do so outside of RStudio.
>
> I find this approach preferable to viewing my ggplot in RStudio's Plots-pane, because it gives you a more accurate preview of how your plot will look in its final context. The preview in RStudio actually doesn't do this, because the scale and size of the plot adjusts to the size you dragged the Plots-pane to.
>
> Here is a gist of how I used to apply this approach, but nowadays I wrapped all of this into my own function.

7 Color, Shape and More

In ggplot2, the aesthetics of your plot, such as color and shape, can be adjusted to enhance the visual representation of your data. In this section, we will explore how to manipulate these aesthetics using the `geom_point()` function.

First, let's recreate our `myplot` object, but this time without the `geom_point()` layer. This will provide us with a clean slate to experiment with:

```r
myplot <- ggplot(data = PlantGrowth) +
  aes(y = weight, x = group) +
  scale_y_continuous(
    name = "Weight (g)",
    limits = c(0, NA),
    breaks = seq(0, 6),
    expand = expansion(mult = c(0, 0.05))
  ) +
  scale_x_discrete(
    name = "Treatment Group",
    labels = c(
      ctrl = "Control",
      trt1 = "Treatment 1",
      trt2 = "Treatment 2"
```

```
    )
  ) +
  theme_classic()
```

7.1 General Aesthetic Modifications

To show you what is possible with `geom_point()`, let's create two new plots. In the first plot, we will set the color of the points to orange. In the second plot, we will modify several aspects of the points, including color, shape, size, and transparency.

```
myplot +
  geom_point(color = "orange")
```

```
myplot +
  geom_point(
    color = "purple",
    shape = 18,
    size = 5,
    alpha = 0.5
  )
```
In the first plot, we use color = "orange" inside the geom_point() function. This sets the color of all points to orange.

In the second plot, we modify several aspects of the points:

- color = "purple" sets the color of the points to purple. shape = 18 changes the shape of the points. ggplot2 includes several different shapes that you can use. The number 18 corresponds to a filled diamond shape.
- size = 3 increases the size of the points. The size is measured in mm.
- alpha = 0.5 sets the transparency of the points. The alpha value ranges from 0 (completely transparent) to 1 (completely opaque).

These modifications allow us to customize the appearance of the points to suit our preferences and the needs of our data.

7.2 Aesthetic Mapping with aes()

One of the most powerful features of ggplot2, however, is its ability to create **dynamic** visual mappings through the **aes()** function. This function is used within ggplot to map data variables to visual properties of the plot, such as color, size, shape, and more. Of course, you are already aware that we have been using **aes()** to define the x and y axes throughout our tutorial.

At its core, `aes()` stands for aesthetic mapping. It's the tool we use to tell ggplot2 how to use the data to modify the appearance of the geoms. For example, if we want to use different colors to represent different groups within our data, `aes()` is how we make that happen.

Finally note that you can define `aes()` and `data =` in general or per individual `geom_`. Thus, these two codes produce the same graph:

```
ggplot(data = PlantGrowth) +
  aes(y = weight,
      x = group,
      color = group) +
  geom_point()
```

```
ggplot() +
  geom_point(
    data = PlantGrowth,
    aes(y = weight,
        x = group,
        color = group)
  )
```
As a result, we can once more change color, shape, size, and transparency, but this time dynamically. As an example color and shape are mapped so they depend on the group, while size and transparency depend on the weight:

```
myplot +
  geom_point(aes(
    color = group,
    shape = group,
    size = weight,
    alpha = weight
  ))
```

Just like we used `scale_x_*` and `scale_y_*` to control the appearance of `aes(x = ..., y = ...)`, there are also scale functions for each aesthetic allowing us to have complete control over the appearance of our plots:

```
myplot +
  geom_point(aes(
    color = group,
    shape = group,
    size = weight,
    alpha = weight
  )) +
  scale_color_manual(
    values = c("orange", "gold", "#00923f")
  ) +
  scale_shape_manual(
    values = c(15, 18, 19)
  ) +
  scale_size_continuous(
    range = c(1, 10)
  ) +
  scale_alpha_continuous(
    range = c(0.1, 0.4)
```

```
)
```

7.3 More on color

I believe color is such an essential aesthetic element in data visualization that it warrants a more detailed exploration.

You don't actually have to manually choose colors for `scale_color_manual()` from long lists of possible colors like this one. Instead, you can utilize functions from various packages that generate the necessary number of colors from predefined palettes via packages like {RColorBrewer} or {METBrewer}.
```
color_vector <- RColorBrewer::brewer.pal(3, "Dark2")

myplot +
  geom_point(aes(color = group), size = 5) +
  scale_color_manual(values = color_vector)
```
```
color_vector <- MetBrewer::met.brewer("VanGogh2", 3)

myplot +
  geom_point(aes(color = group), size = 5) +
  scale_color_manual(values = color_vector)
```

But in some cases, you don't even have to first generate a vector and then pass it to `scale_color_manual()`. Instead, you can directly use the respective `scale_color_*` function, which automatically selects and applies colors from a palette.

```
myplot +
  geom_point(aes(color = group), size = 5) +
  scale_color_brewer(palette = "Pastel1")
```
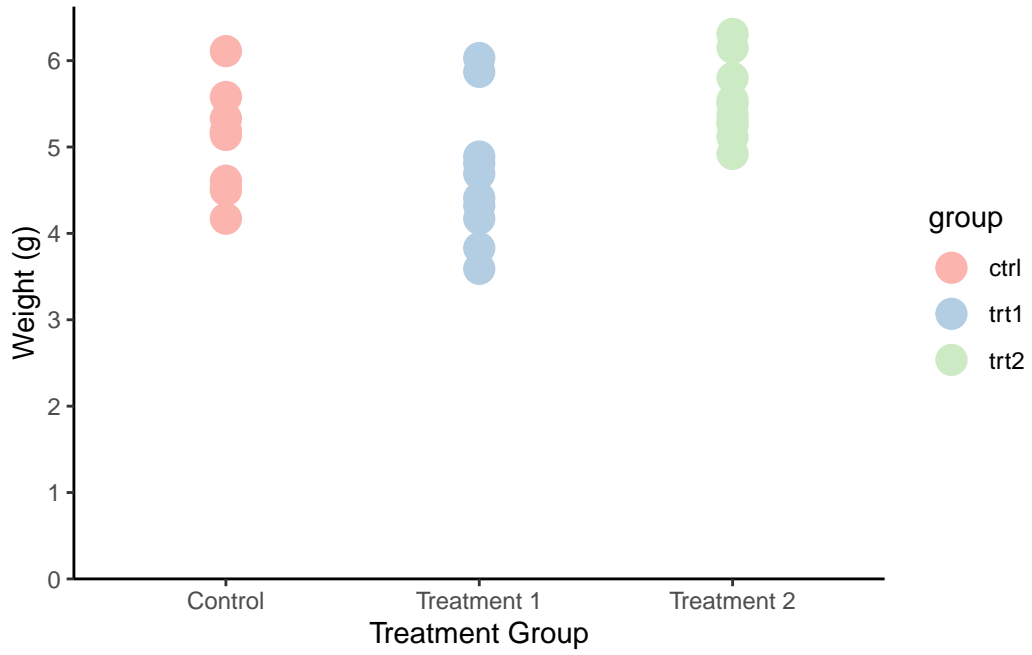

```
myplot +
  geom_point(aes(color = group), size = 5) +
  scale_color_viridis_d()
```
Note that there are actually color palettes that are **color-blind friendly** like viridis, which was used above via `scale_color_viridis_d()`.

Finally, you sometimes must not or don't need to choose the colors at all, because there is a corporate design you can stick to. Maybe you even just try to match other colors appearing in the document/journal that the graphic will end up in. As an example, this is a screenshot of the Corporate Design of the German Federal Environment Agency

	Farbname	Euroskala	RGB	Pantone	Hex	RAL
1	UBA Grün	68/0/95/0	94/173/53	368	#5EAD35	6018
	UBA Dunkelgrün	85/0/100/35	0/118/38	356	#007626	6001
2	UBA Blau	80/20/0/0	0/155/213	2925	#0b90d5	5012
	UBA Dunkelblau	80/20/0/50	0/95/133	2955	#005f85	5001
